Abstract

The Observed Perlmutter-Riess Acceleration (OPRA) implies that the expansion of the Universe is currently increasing and is motivation for the so-called phantom energy models. We consider the dynamics of phantom scalar field models. An important physical time constraint, which can be used to rule out many cosmological models, is obtained from the condition that all forms of energy density, including the field causing OPRA (e.g., the phantom field), must be non-negligible for an extended period, which is conservatively estimated to be of the order of a few *Gyr*. We find that this physical time constraint cannot be satisfied in conventional phantom cosmological models.

1 ACT I: OPRA

Evidence from supernovae observations [1] strongly suggest the possibility of late-time accelerated expansion of the Universe; the Observed Perlmutter-Riess Acceleration (OPRA). The energy density is usually described by an effective “equation-of-state” parameter $\gamma_{eff} - 1 \equiv p/\rho$, the ratio of the energy pressure p to its energy density ρ . A value $\gamma_{eff} < 2/3$ is required for cosmic acceleration. The most recent observations, including supernovae, cosmic microwave background experiments, quasar-lensing statistics and galaxy clustering observations (see [2] and references therein), taken together suggest a Universe with γ_{eff} satisfying $\gamma_{eff} \leq 0$; this is consistent with $\gamma_{eff} = 0$,

but it has been argued that with certain prior assumptions the best fit is actually for $\gamma_{eff} < 0$ [2, 3]. It is therefore important to look for theoretical possibilities to describe dark energy with $\gamma_{eff} < 0$.

A wide class of scalar field cosmologies have been utilized to model dark energy. Quintessence models [4] lead to $0 < \gamma_{eff} < 2/3$. The simplest explanation for dark energy is a cosmological constant, for which $\gamma_{eff} = 0$. Matter with $\gamma_{eff} < 0$ has been dubbed “phantom energy” [2], and has received increased attention recently [5]. Specific models with non-minimally coupled scalar fields may lead to phantom energy; perhaps the simplest alternative is provided by a phantom scalar field with negative kinetic energy. Theorists have also discussed stringy phantom energy [6] and brane-world phantom energy [7].

Models with a constant $\gamma_{eff} < 0$ lead to a future singularity commonly called the *Big Rip*. This singularity is typically characterized by a divergent pressure and acceleration in a finite proper time (although there are rip-free phantom cosmologies and there are also sudden future singularities that are less severe [8]). The energy density of phantom field increases and eventually violates the dominant energy condition. The physical consequences in this scenario have been discussed in [3]. Expanding universes that come to a violent end after a finite proper time at a future Big Rip singularity have a number of additional undesirable properties [9].

In this paper we take a conservative view and we will only analyze the cosmological dynamics of the phantom field and relate it to observations. The dynamics of phantom cosmology has been discussed previously [5, 11].

2 ACT II: The Phantom

The Einstein equations in a Robertson-Walker spacetime containing phantom matter and a separately conserved perfect fluid are

$$2\dot{H} = -(\rho_b + p_b + \rho_{ph} + p_{ph}) + \frac{2k}{3a^2} \quad (1)$$

$$3H^2 = (\rho_b + \rho_{ph}) - \frac{3k}{a^2}, \quad (2)$$

$$\dot{\rho}_b + 3H(\rho_b + p_b) = 0, \quad (3)$$

where $a(t)$ is the expansion scale factor, k is the curvature parameter, and $H = \dot{a}/a$ is the Hubble expansion rate. In the above we have assumed that

the perfect fluid satisfies the barotropic equation of state

$$p_b = (\gamma - 1)\rho_b, \quad (4)$$

where γ is a constant which satisfies $0 < \gamma < 2$.

In the best motivated models the phantom cosmologies are generated by a (separately conserved) scalar field with negative kinetic term. The energy density and pressure of the field are given by

$$\rho_{ph} = -\frac{1}{2}\dot{\phi}^2 + V(\phi), \quad (5)$$

$$p_{ph} = -\frac{1}{2}\dot{\phi}^2 - V(\phi). \quad (6)$$

The corresponding equation of state parameter is now given by $(\gamma_{ph} - 1) \equiv p_{ph}/\rho_{ph} < 0$, for $\rho_{ph} > 0$. The effective Klein-Gordon equation reads

$$\ddot{\phi} + 3H\dot{\phi} - \frac{dV}{d\phi} = 0. \quad (7)$$

We shall consider a self-interacting scalar field with an exponential potential

$$V = V_0 e^{\kappa\phi}, \quad (8)$$

where V_0 and κ are positive constants. We note that a qualitative analysis of the standard spatially homogeneous and isotropic scalar field models has shown that there exist scaling solutions which can act as unique late-time attractors in these models [10].

2.1 Dynamics

Defining

$$\Phi \equiv \frac{\dot{\phi}}{\sqrt{6}H}, \quad \Psi \equiv \frac{V}{3H^2}, \quad \Omega_b \equiv \frac{\rho_b}{3H^2}, \quad (9)$$

and the new logarithmic time variable τ by

$$\frac{d\tau}{dt} \equiv H, \quad (10)$$

the governing equations can be written as the three-dimensional autonomous system:

$$\Phi' = \sqrt{\frac{3}{2}}\kappa\Psi + \frac{3}{2}\Phi \left[\left(\gamma - \frac{2}{3} \right) \Omega_b - \frac{2}{3}(2 + 2\Phi^2 + \Psi) \right], \quad (11)$$

$$\Psi' = 3\Psi \left[\sqrt{\frac{2}{3}}\kappa\Phi + \left(\gamma - \frac{2}{3} \right) \Omega_b - \frac{2}{3}(2\Phi^2 + \Psi - 1) \right], \quad (12)$$

$$\Omega_b' = 3\Omega_b \left[\left(\gamma - \frac{2}{3} \right) (\Omega_b - 1) - \frac{2}{3}(2\Phi^2 + \Psi) \right], \quad (13)$$

where a prime denotes differentiation with respect to τ , and the Friedmann equation becomes

$$1 - \Omega_b - (\Psi - \Phi^2) = -k/a^2 H^2 \quad (14)$$

The physical region of the state-space is constrained by the requirement that the energy densities be non-negative; i.e., $\Omega_b \geq 0$ and $\Omega_{ph} \equiv (\Psi - \Phi^2) \geq 0$. Furthermore, from equation (14) we find that the variables Ω_b and Ω_{ph} are bounded for $k = 0$ and $k = -1$, but not for $k = +1$. The individual variables need not be bounded. Note that $\Omega_{ph} = 0$ is *not* an invariant set.

Geometrically the zero-curvature models ($k = 0$) are represented by $\Omega_b - \Phi^2 + \Psi = 1$, in the (Φ, Ψ, Ω_b) state-space. Defining $\mathcal{K} = 1 - \Omega_b - (\Psi - \Phi^2)$, we see that

$$\mathcal{K}' = \mathcal{K} \left[3 \left(\gamma - \frac{2}{3} \right) \Omega_b - 2(2\Phi^2 + \Psi) \right], \quad (15)$$

so that $\mathcal{K} = 0$ is an invariant set.

2.1.1 Equilibrium points at finite values

The equilibrium points $(\Phi_0, \Psi_0, \Omega_{b0})$ in the physical phase space at finite values are:

M $(0, 0, 0)$: eigenvalues $[-2, 2, (2 - 3\gamma)]$ (*saddle*). The exact solution corresponding to this equilibrium point is the Milne model.

F $(0, 0, 1)$: eigenvalues $[-\frac{3}{2}(2 - \gamma), 3\gamma, (3\gamma - 2)]$ (*saddle*). The exact solution corresponding to this equilibrium point is the flat Friedmann model.

R $(\frac{\kappa}{\sqrt{6}}, 1 + \frac{\kappa^2}{6}, 0)$: eigenvalues $[-(2 + \kappa^2), -3(1 + \frac{\kappa^2}{6}), -(3\gamma + \kappa^2)]$ (*sink*). The exact solution corresponds to a future late-time singularity called the Big Rip singularity. In this power-law solution [5]

$$a = a_0(-t)^{-2/\kappa^2}, \quad (16)$$

$$V = \frac{2(6 + \kappa^2)}{\kappa^4} e^{\kappa\phi}, \quad (17)$$

$$\phi = \frac{-2}{\kappa} \ln |t|. \quad (18)$$

This solution represents a universe in which the scale factor grows monotonically till a future Big Rip is reached at $t = 0$. In our models, $\rho > 0$ but the weak energy condition is violated because $\rho + p \sim -\dot{\phi}^2 < 0$. From (16), the effective barotropic index for the power-law phantom field solution is $\gamma_{ph} = -\dot{\phi}^2/\rho_{ph} = -\kappa^2/3$ which becomes negative while both the energy density ρ_{ph} and the pressure p_{ph} of the field diverge (at $t = 0$).

We note that there are *no equilibrium points corresponding to matter scaling solutions*, in which both ordinary/dark matter and phantom matter are non-negligible ($\Phi_0^2 + \Psi_0 \neq 0, \Omega_{b0} \neq 0$ [10]. This was noted in [11]. In addition, it was shown [12] that there are no matter scaling solutions in two scalar field models (with exponential potentials).

2.1.2 Equilibrium points at infinity

We need to consider what happens if the variables diverge. This can occur if $H = 0$, thus leading to bouncing models [13]. Let us therefore assume that $k \leq 0$ and $\Phi, \Psi \rightarrow \infty$. From the equations of motion we note that this can only happen to the past. In fact, the variables (including Ω_b) will in general diverge to the past; asymptotically, we find

$$\Phi^2, \Psi, \Omega_b \propto \frac{1}{\tau - \tau_0}, \quad \tau > \tau_0, \quad (19)$$

and hence, the variables blow up in finite τ . This blow-up is only an artifact of the variables chosen and results because the universe experiences a bounce. In principle, alternative dimensionless variables can be chosen to render the state space compact, even when the universe bounces. More details are presented in [16].

A more serious problem with these models is the behaviour of the phantom energy density. We find that $\Omega_{ph} = \Psi - \Phi^2$ goes negative into the past, and that the models, without modifications, are not physical [16].

2.2 Alternative Phantoms

There is an alternative approach to obtaining Big Rip singularities in which the phantom energy is modelled as a (separately conserved) perfect fluid with

effective equation of state $p_{ph} = (\gamma_{ph} - 1)\rho_{ph}$, where $\gamma_{ph} < 0$ is a constant. Defining normalized variables, all equilibrium points are found to have either Ω_b or Ω_{ph} zero, and hence again there are no matter scaling solutions. Indeed, defining $\chi = (\Omega_{ph} - \Omega_b)/(\Omega_{ph} + \Omega_b)$, we find that χ is monotonically increasing from $\chi = -1$ to $\chi = +1$. These models cannot be physical.

It has been noted that matter scaling solutions are not possible in phantom scalar field models with other potential [11]. However, scaling solutions are possible if there are interactions allowed between the phantom field and the background matter fields [17]; the physical consequences of these interacting models remain to be fully investigated.

3 ACT III: the Phantom Unmasked?

The physical models need to satisfy a number of observational constraints. In general, the Universe is approximately flat (but has non-zero curvature), the Hubble time H_0^{-1} corresponds to $h = 0.71 \pm 0.06$ [18], and it is strongly indicated that presently 5 percent of matter is due to baryons/ordinary matter, 25 percent dark matter, and 70 percent dark energy. The coincidence problem (or fine tuning problem) asks why are the matter density, scalar density, and phantom density comparable at the present epoch.

In particular, the matter and scalar fields must be non-negligible for an extended period in order to be consistent with galaxy formation, the existence of dark matter and OPRA. This is difficult to achieve in regular cosmology, although it can be accomplished in matter plus scalar field models due to the existence of a matter scaling solution [10], which corresponds to an equilibrium point in a dynamical systems analysis (but not necessarily an attractor; usually in the presence of curvature this equilibrium point is a saddle, and if trajectories move close to this saddle, the trajectories will stay close for an arbitrarily long period of time before subsequently evolving away).

The transition from deceleration to acceleration occurs at redshift $z_T > 0.4$ [15, 14], and can be higher depending on the parameters of the model; this redshift corresponds to $t_T = 0.6t_0$, where t_0 is the present time. Consequently, the time period during which the phantom field must be non-negligible, $\mathbf{t}_{ph}$, satisfies $\mathbf{t}_{ph} > t_0 - t_T \sim \frac{1}{4}(H_0^{-1})$.

In the theory of structure formation the present day galaxies and galaxy clusters formed due to gravitational instability of initially small primordial density fluctuations [15]. Thus the time $\mathbf{t}_b$ for which the matter is non-

Figure 1: The evolution of the phantom energy density, Ω_{ph} , and the energy density of matter, Ω_b , in terms of the logarithmic time τ .

negligible must be at least as long as the age of globular clusters [18]: consequently, $\mathbf{t}_b > 12.0 \text{ Gyr}$. We also note that $\mathbf{t}_{dm} > t_0 - t_{rec}$.

We shall not impose all of these constraints here, but simply consider the condition that all forms of energy density must be non-negligible for an extended period, which we very conservatively estimate to be $\mathbf{t} = \frac{\ell}{10}(H_0^{-1})$, where ℓ is of order unity, or a few *Gyr*.

3.1 Discussion

In the models we start with the phantom field energy density being dominated by the density of the ordinary matter. That is, we begin the evolution close to the equilibrium point **F**. Eventually the energy density of the phantom field dynamics "switches on" (the precise details depending on the shape of the phantom field potential $V(\phi)$ [5]). The model then evolves towards the equilibrium point **R**.

Numerical experiments were performed for different initial conditions. The results presented in Figure 1 are typical. In Figure 1, Ω_b and Ω_{ph} are only non-negligible for a very brief period. Ω_b changes from unity to zero, as it moves away from the equilibrium point **F** towards the sink **R**, at an exponential rate (similarly for Ω_{ph}). For all numerical values (and for all

values of k) we find that $\mathbf{t}$ is negligible, and the physical time constraint cannot be satisfied. We note from Figure 1 that during the epoch in which Ω_b and Ω_{ph} are non-negligible, the curvature is also non-negligible, which is not consistent with current observations. By choosing particular initial conditions (fine-tuning), we can arrange for the curvature to be small. But no amount of fine-tuning can allow for a significant $\mathbf{t}$. Hence these models are not physical. We emphasise that this *physical time constraint is a very severe constraint and can be used to rule out many cosmological models*.

The behaviour to the past (which does depend on the sign of k) was briefly discussed above. The numerics confirm that in all cases Ω_b crosses unity at a finite time in the past, whence Ω_{ph} becomes negative and eventually the variables diverge. Presumably additional terms must be added to the models to avoid this type of unphysical behaviour.
